I. INTRODUCTION

TODO

Cognitive radio.

The cognitive radio purposes is to exploit opportunistically the underused electromagnetic spectrum. The spectrum access is a significant problem because it depend on the legally defined by different agency (e.g FCC: Federal Communications Commission) [1]. The spectrum licensed is occupied principally by the primary user. the frequency holes is appearance at particular periods of time and specific geographic location when the licensed frequency band is free and not used by that user. The utilization can be improved by allowing to the secondary user a temporarily occupation of the spectrum holes. The Dynamic Spectrum Access (DSA) networks is the secondary opportunistic user of the spectrum without interfering with the primary user [2]. The cognitive radio with an efficient DSA is implemented on the reconfigurable Software Defined Radio (SDR) [3]. The optimal performances of the secondary user is obtained by the capability to adapt to the surrounding environment. This environment is characterized by the sensed informations, such as transmission frequency, bandwidth, power consumption, noise power, modulation, etc [2].

Adaptive modulation and channel to improve data rate.

Nodes consensus for wireless transmission improvement.

TODO

III. PROBLEM DEFINITION

The purpose of our work is to achieve a hight network throughput or spectrum efficiency with a selection of the appropriates parameters. The efficiency is measured by the

utility function which is defined to carry out a balance between the power consumption, the modulation technique and the channel quality with existence of primary and secondary users.

We start our problem formulation by expressing the Signal Interference Noise Ratio (SINR) in terms of the power transmission, the gain and the thermal noise. Let N denotes a set of cochannel labelled by the integers $i = 1, 2, \dots, N$. Where G_{ij} defines the path gain from node j to node i . P_i indicates the transmission power of node i . The signal is represented when $i = j$, otherwise, this is interference. The SINR of node i , γ_i is given by :

$$\gamma_i(P_i) = \frac{G_{ii}P_i}{\sum_{j \neq i} G_{ij}P_j + n_i} \quad (1)$$

$$\gamma_i(P_i) = \frac{G_{ii}P_i}{I_i}$$

The value of n_i denotes the receiver thermal noise power. The total interference and thermal noise are gathered in I_i .

The channel capacity C_i of channel is modelled as function of the frequency bandwidth ω and $\gamma_i(P_i)$ [4].

$$C_i = \int_0^\infty \omega \log_2(1 + \gamma_i) Pr(\gamma_i) d\gamma_i \quad (2)$$

Also, the capacity can be expressed as function of the adjusted transmit power $P_i(\gamma_i)$ to the fading channel [5]. The parameter $P_i(\gamma)$ is the adaptive power relative to γ , subject to the average power constraint \bar{P}_i .

$$C_i = \max_{\int P_i(\gamma_i) Pr(\gamma_i) d\gamma_i = \bar{P}_i} \int_0^\infty \omega \log_2 \left(1 + \frac{P_i(\gamma_i) \gamma_i}{\bar{P}_i} \right) Pr(\gamma_i) d\gamma_i \quad (3)$$

To maximize the channel capacity in (3), the power adaptation is given by :

$$\frac{P_i(\gamma_i)}{\bar{\gamma}_i} = \begin{cases} \frac{1}{\gamma_i^0} - \frac{1}{\gamma_i} & , \gamma_i \geq \gamma_i^0 \\ 0 & , \gamma_i < \gamma_i^0 \end{cases}$$

Where γ_i^0 is some "cutoff" value, when $\gamma_i^t < \gamma_i^0$ at time t , then no power is allocated to the i th channel. The variation of γ in the time depend on the probability distribution Pr . In the case of the favorable channel more power is allocated for transmission. In contrast, less power will be transmitted. The channel is not used if the value of γ_i drops down below γ_0 .

The number of bits transmitted within each symbol is restricted to a finite number of values. With M -QAM The constellation size is restricted to $M = 2^j, j = 1, 2, \dots, J$, making the bits per symbol equal to one of a small set of values. The data rate of one channel is defined here as the number of bits that can be successfully received within each transmitted symbol. However, the Bit Error Rate BER affect the data rate and it can be approximated for each specific modulation (e.g MPSK, M -QAM) [6]. We restrict our work to MQAM signal constellations. For fixed M value and symbol period T , the data rate R of MQAM modulation

[7] family is equal to:

$$R = [\log_2 M_j - 1]/T$$

On the other hand, the BER is given by the expression [5] :

$$BER \approx 0.2 \exp \left[\frac{-1.5\gamma}{(M-1)} \frac{P_i(\gamma)}{\bar{P}_i} \right] \quad (4)$$

To maintain a fixed BER , in the equation (5), we can adjust M and $S(\gamma)$

The adaptive modulation is used to maintain a constant BER and to increase the spectral efficiency (bis/s/Hz) when wireless channel quality changes. The hight spectral efficiency average is obtained by transmitting at hight data rate when channel conditions are favorable and low data rate when the channel degrades. From (4), the constellation size is expressed in terms of γ_i fade level and the transmit power p_i adapted to the interference.

$$M(\gamma_i) = 1 + \frac{1.5\gamma_i}{-\ln(5BER)} \frac{P_i(\gamma_i)}{\bar{P}_i} \quad (5)$$

IV. SYSTEME MODEL

TODO : Global view

A. CR network preferences

Network of cognitive radio agents n_i is defined with topology $G = (V, E)$ in which each agent only communicates with its neighboring agents $\Upsilon_i = \{j \in V : \{i, j\} \in E\}$ which are inside a range of radius R . Each cognitive radio agents can communicate through several communication profiles $\rho_0, \rho_1 \dots \rho_M$ composed of available bandwidth, channel number, etc.

Communication profile definition : Add ρ_j definition !:
[TODO - Rafik]

A profile preference preorder is representative of all node i if for all of them, this preorder is established. Profile preferential preorder of CR communication profile is modelled by Von-Neumann preferential utility [REF]. Metric value of preference preorder is modelled through an inequality of utility function u^i such as in eq 6.

$$\forall k, \rho_j \succ \rho_k \iff \forall i, k, \rho_j \succ_i \rho_k \iff \forall k, u_j > u_k \quad (6)$$

TODO : OWA et PARETO

Based on this definition, node preference preorder must evolved to converge to an aggregated preference preorder which is representative of the set of node preference preorder to verify definition given in eq 6. In this paper, the aggregation operator studied is the profile utility average through distributed network average consensus.

B. Distributed utility aggregation

Average consensus of preferences is composed of M average consensus problems to determine a representative utility value for each profile ρ to produce an order of profile utility for all CR network by a distributed way. Distributed network consensus problems is solved asymptotically by using gradient-descent algorithm in which \bar{u}_j are the final average consensus value of initial utility of node i for profile j as summarize in eq 7 (more details about network average consensus can be found in [REF]).

$$\bar{u}_j = \lim_{t \rightarrow +\infty} u_j(t) = \frac{1}{N} \sum_{i=0}^N u_j^i(0) \iff \forall i, j ||\dot{u}_j - \bar{u}_j|| < \varepsilon \quad (7)$$

The iterative algorithm of distributed average network consensus is given in eq 8 with its analytic form and in eq 9 with its matrix form and the necessary condition of convergence : $\forall i, W^i < \frac{1}{\Delta}$ with $\Delta = \max(\#\Upsilon_i)$.

$$u_j^i(t+1) = u_j^i(t) - w^i \sum_{k=0}^N [u_j^i(t) - u_j^k(t)] \quad (8)$$

$$U_j(t+1) = [I - WL]U_j(t) \quad (9)$$

with L the Laplacian of network G defined in eq 10 in which A is adjacency matrix of graph G and D a diagonal matrix defined as $L_{i,i} = \#\Upsilon_i$.

$$L = D - A = \begin{cases} L_{i,i} = \#\Upsilon_i \\ L_{i,j} = \begin{cases} -1 & \text{if } j \in \Upsilon_i \\ 0 & \text{else} \end{cases} \end{cases} \quad (10)$$

By applying network average consensus for each profile preference, each node obtains the same set of average profile aggregated preference utility according to interval error $]-\varepsilon + \dot{u}; \dot{u} + \varepsilon[$ produced by asymptotic convergence.

C. Robust uniqueness decisions

Decision rules allows nodes to choice between profiles according to the aggregated utility of profile preferences estimated by previously presented network average consensus. Nodes must make the same choice and so, decision rules have to be strongly discriminant as defined in eq 11 to allow decisions to be uniqueness.

Theorem 1. *If only if it exists a profile utility \dot{u}_j^i greater than any other profile utility \dot{u}_k^i for any decision makers i estimated by network average consensus, so that it's ideal average utility value \dot{u}_j is spaced more than 2ε from any other ideal average utility value \dot{u}_k then this profile is preferred to any other profile by all decision makers.*

$$\forall i, k, \exists j / \dot{u}_j^i > \dot{u}_k^i \ \& \ ||\dot{u}_j - \dot{u}_k|| > 2\varepsilon \iff \rho = \rho^i = j \quad (11)$$

Proof: Network average consensus converge to average value \dot{u} of node initial value $u(0)$ for any network topology if convergence rate of gradient descent algorithm is limited to $\frac{1}{\Delta}$ with $\Delta = \max(\#\Upsilon_i)$ [REF]. Average value \dot{u} is unique by definition, so the set of utility order $u_0(0)^i > \dots > u_M(0)^i$ of each nodes i will evolve to an unique average utility order $\dot{u}_k > \dots > \dot{u}_l$ according to convergence error ε which defines an error interval $]-\varepsilon + \dot{u}; \dot{u} + \varepsilon[$.

Assume that there exists a node which prefers a profile j different from the other node preferences. This can be happen if and only if, interval error of this preference utility is juxtaposed to an another interval error of another near preference utility $]-\varepsilon + \dot{u}_j; \dot{u}_j + \varepsilon[\cap]-\varepsilon + \dot{u}_k; \dot{u}_k + \varepsilon[\neq \emptyset$. By rewriting it by using triangle inequality, $\forall i, ||\dot{u}_j - \dot{u}_k|| < ||\dot{u}_j - \dot{u}_j^i|| + ||\dot{u}_k - \dot{u}_k^i||$. Now, $||\dot{u}_j - \dot{u}_k|| > 2\varepsilon$, so $||\dot{u}_j - \dot{u}_j^i|| + ||\dot{u}_k - \dot{u}_k^i|| > 2\varepsilon$ must be true. But, $\forall i, l, ||\dot{u}_l - \dot{u}_l^i|| < \varepsilon$ by consensus convergence definition, so it is impossible that $||\dot{u}_j - \dot{u}_j^i|| + ||\dot{u}_k - \dot{u}_k^i|| > 2\varepsilon$. If a node has another preference than the other node, its preference utility cannot be spaced from its other preference utility from more than 2ε . ■

Definition 1. *Two profiles \dot{u}_i and \dot{u}_j are defined equivalent if their estimated aggregated utility value is inferior than 2ε .*

$$\rho_i \sim \rho_j \iff ||\dot{u}_i - \dot{u}_j|| < 2\varepsilon \quad (12)$$

Based on theorem 1 and definition 1, a uniqueness profile decision rule can be defined such as in eq 13. Theorem 1 guarantees that it is possible to build a unique aggregated preorder of preferences which is representative of average profile preference utility of all nodes where it exists an interval enough discriminant. Definition 1 defined equivalence state if it do not exist.

Finally, space U is the set of equivalent best aggregated profile preference utility on which are applied an arbitrary rule to select one unique and common decision ρ

$$\rho = \begin{cases} U \in \mathbb{N} / j, k \in U \text{ if } \forall l, i, \rho_j \sim_i \rho_k \succ_i \rho_l \\ \rho_i = \min(U) \end{cases} \quad (13)$$
